Bug localization represents one of the most expensive, as well as time-consuming, activities during software maintenance and evolution. To alleviate the workload of developers, numerous methods have been proposed to automate this process and narrow down the scope of reviewing buggy files. In this paper, we present a novel buggy source-file localization approach, using the information from both the bug reports and the source files. We leverage the part-of-speech features of bug reports and the invocation relationship among source files. We also integrate an adaptive technique to further optimize the performance of the approach. The adaptive technique discriminates Top 1 and Top N recommendations for a given bug report and consists of two modules. One module is to maximize the accuracy of the first recommended file, and the other one aims at improving the accuracy of the fixed defect file list. We evaluate our approach on six large-scale open source projects, i.e. ASpectJ, Eclipse, SWT, Zxing, Birt and Tomcat. Compared to the previous work, empirical results show that our approach can improve the overall prediction performance in all of these cases. Particularly, in terms of the Top 1 recommendation accuracy, our approach achieves an enhancement from 22.73% to 39.86% for ASpectJ, from 24.36% to 30.76% for Eclipse, from 31.63% to 46.94% for SWT, from 40% to 55% for ZXing, from 7.97% to 21.99% for Birt, and from 33.37% to 38.90% for Tomcat.

Keywords: Software engineering; bug localization; information retrieval; bug report.

1. Introduction

Bug tracking systems (BTSs) are a class of dedicated tools to keep track of bug-related issues for software projects. They provide critical supports and are widely used by developers during software development and maintenance phases. Usually, a new software project may set up an account in a robust BTS, such as Bugzilla, to gather potential defects. If multiple shareholders of the software, such as developers, testers or even users, come across a defect, they can resort to the BTS and create an issue report to describe the situation. When a bug report is received and confirmed, it will be assigned to a developer for fixing [1]. The developer must first carefully read the bug report, especially the descriptive parts (e.g. “Summary” and “Description”) and elicit the keywords such as class names or method names, and then review source code files to find and fix the buggy parts. The above activity is indeed time-consuming and tedious, especially for large projects with thousands of source files. Manual localization requires high expertise and imposes a heavy burden to developers, which inevitably hampers productivity. Therefore, it is highly desirable to automate this process and recommend potential buggy source files to developers with a given bug report.

In recent years, some researchers have proposed various approaches to produce a ranking list of buggy files for processing a bug report [2]. The ranking list can narrow down a developer’s search scope and thus help enhance debugging productivity. The basic technique of these approaches is standard information retrieval (IR). It returns a ranking list of buggy files based on the similarity scores between the textual parts of a bug reports and the source code. However, the important information of bug reports does not only come from the textual information, but also from other parts. For example, Sisman et al. extended the IR framework by incorporating the histories of defects and modifications stored in versioning tools [3]. The histories might complement the vague description in the textual parts of the bug reports and improve the accuracy of ranking buggy files. Indeed, the source files are coded in some specific programming language, such as Java or C++, which, compared to natural languages, have different grammatical/semantic features. Therefore, traditional natural language processing techniques from IR field cannot be applied directly to extract the discriminative features of the source code. In light of this, Saha et al. utilized code constructs and presented a structured IR-based technique [4]. They divided the code of each file into four parts, namely, Class, Method, Variable and Comments. Furthermore, the similarity score between a source file and a bug report was calculated by summing up the eight similarity scores between the source files and bug reports. In [1], Zhou et al. integrated the information of file length and similar bugs to strengthen the traditional Vector Space Model. After that, many other researchers have explored combining other attributes of the bug reports and the source code to further improve the accuracy of bug localization [5–7].

We observe that most of the existing work, if not all, treats the words (apart from stop words) equally without discrimination. To be more specific, they do not consider
the part-of-speech (POS) features of underlying words in the bug reports. The part-of-speech, simply “POS” or “PoS” for short, represents any particular category of words which have similar grammatical properties in nature language, such as noun, verb, adjective, adverb, conjunction, etc. Words with the same part of speech generally display similar behavior in terms of syntax, and play similar roles within the grammatical structure of sentences. In reality, to understand the meaning of a bug report, POS of each word in a sentence is of particular importance. For example, after traditional IR-based preprocessing, the summary of Eclipse Bug Report #84078: “RemoteTreeContentManager should override default job name” is transformed into “RemoteTreeContentManager override default job name”. The noun “RemoteTreeContentManager” directly indicates the buggy file, and the noun phrase “job name” is the substring of a method in the buggy file. By contrast, the verb “override” does not exist in the defect file and the adjective “default” is not a discriminative word for Java code. Thus, these words actually provide very little help during debugging.

Textual similarity can indeed help identify potential buggy source files. For example, Fig. 1 illustrates a textual snippet of a real bug report (ID: 76255) from Eclipse 3.1 and the bug-fix information. Both the summary and the description focus on the source file “AntUtil.java” and the file is indeed at the first place of the ranking list, but the rest two fixed files “AntElementNode.java” and “AntNode.java” contributing to this defect are at the 4302nd and the 11459th places on the same list ranked solely by similarity [1]. In this case, we observe that most fixed files for the same bug report have invocation relationship between them. For example, the file “AntUtil.java” invokes the other two files. Such underlying logical relationship cannot be captured by the grammatical similarity. This fact motivates us to combine the invocation information with the traditional IR-based methods to improve the accuracy of buggy source files identification.

In [8], Kochhar et al. investigated the potential biases in bug localization. They defined “localized bug reports” in which the buggy files have been identified in the report itself. Namely, the class names or method names of the buggy files exist in the bug reports. Motivated by this, in our approach, we filter the source files and only

```
Bug ID: 76225
Summary: Move the ExternalAntBuildfileImportPage to use the AntUtil support.
Description: The ExternalAntBuildFileImportPage duplicates a lot of functionality now presented in AntUtil.
Fixed Files:
org.eclipse.ant.internal.ui.AntUtil.java
org.eclipse.ant.internal.ui.model.AntElementNode.java
org.eclipse.ant.internal.ui.model.AntModel.java
```

Fig. 1. Bug report example.
preserve the class names and method names to reduce the noisy localization for the localized bug reports. However, this process also introduces potential issues. If a bug report is a localized one, this method indeed can lift up the rankings of its buggy files. But this filtering strategy could also lift other irrelevant files up to the top places as a side effect. Moreover, if a bug report is not a localized one — for example, the bug report does not contain class names or method names but its buggy files are ranked high on the list — this filtering strategy will reduce their rankings.

In light of the above considerations, we need a more comprehensive approach to combine different sources of information to give a more accurate buggy source file localization based on bug reports. We believe that different types of words in bug reports contribute differently to the bug localization process and are worth treating distinctively. Our approach takes the POS of index terms as well as the underlying invocation relationship into account. In order to take advantages of the localized bug reports and avoid the decrease of global performance, we use different ranking strategies for Top 1 and Top N recommendations, and propose an adaptive approach, taking the demand of the developers into account.

The main contributions of this paper are as follows:

(1) We propose a POS based weighting method to automatically adjust the weight of terms in bug reports. Particularly, we emphasize the importance of noun terms. This method sets different weights to terms from the summary and description parts in bug reports in order to distinguish their importance.

(2) We consider the invocation relationship between source code files to lift up the ranking of the files that are invoked by the file mentioned in bug reports with the highest similarity scores. This method can help increase the global performance, like MRR.\(^a\)

(3) We propose an adaptive approach to maximize the accuracy of recommendations. The approach sets a selection variable \( opt \in \{ \text{true}, \text{false} \} \) for users. We conduct a comparative study on the same dataset in [1], which confirms the performance improvement by our approach.

This paper is based on our previous work [9], but with significant extensions. Firstly, we carry out more extensive experiments: the number of examined open source projects is doubled — from three to six. Accordingly, the number of bugs and source files have been increased from 3459 to 8496 and from 19832 to 32162 respectively, which, to some extent, mitigates the external threats to validity. Secondly, we optimize the process of rendering invocation relationship. In our previous paper [9], we simply used the string-based match to find the invocation files of the highest scored file. This approach is easy to implement, but its performance (implemented in module 2 of our approach; cf. Sec. 4) is rather poor and the invocation relation has to be calculated each time. To mitigate the problem, we leverage Eclipse Plugin CallHierarchy (org.eclipse.jdt.internal.corext.callhierarchy) to

\(^a\)Mean Reciprocal Rank.
statically analyze the source code. This can help extract the invocation relation among source files in a project more accurately and avoid introducing noises. Also, the corpus-based method may explore some implicit, but important, invocation relation. Furthermore, in order to reduce the overhead, we produce the invocation corpus for module 2 which can be reused once derived.

The rest of the paper is organized as follows. Section 2 presents some related research. Section 3 briefly introduces the background of our work. Section 4 describes the POS oriented weighting method and the adaptive defect recommendation approach. We experiment with open source data and discuss the results in Sec. 5. Section 6 discusses the threat to validity, and Sec. 7 concludes the paper.

2. Related Work

Software debugging is time-consuming but also crucial in software life cycles. Software defect localization becomes one of the most difficult tasks in the debugging activity [10]. Therefore, automatic defect localization techniques that can guide programmers are much-needed. Dynamical bug localization approaches can help developers find defects based on spectrum [11]. A commonly-used method of these approaches is to produce many sets of successful runs and failed runs for computing suspiciousness of program elements via program slicing. The granularity of suspiciousness elements can be a method or a statement. Although the dynamic approach can locate the defect to a statement, the generation of test cases and its selection are also complex [12].

Many researchers have tried to use static information of bugs and source code for coarse-grained localization [13]. They proposed some IR-based approaches combining with some useful attributes of software artifacts and defined the suspicious buggy files depending on the similarity scores between bug reports and source files. Usually, IR-based models are used to represent the textual information of the bug report and source code, such as Latent Semantic Indexing (LSI), Latent Dirichlet Allocation (LDA) and Vector Space Model (VSM), which are feasible for numerical calculation [14–16]. In [17], Lukins et al. showed that LDA can be applied successfully to source code retrieval for bug localization and compared with LSI-based approaches. The empirical result suggests LDA-based approach is more effective than the approaches using LSI alone. These works, however, did not consider the POS features of the underlying reports. Gupta et al. [18] attempted to use the POS tagger to help understand the regular, systematic ways a program element is named, but they did not apply the technique to the task of bug localization.

Apart from the efforts in defect localization, there is another thread of relevant work on the bug report classification [19]. Before applying the bug localization techniques, it must be confirmed that the selected bug reports describe the real bugs and then their fixed files are extracted for evaluation, which may save much time and reduce potential noise [8]. A lot of research has been conducted for reducing the noise in bug reports [20]. They used the text of the bug reports and predicted the bug
reports to be bug or non-bug with many techniques [21]. Zhou et al. proposed a hybrid approach by combining both text mining and data mining techniques to automate the prediction process [22]. These works either empirically studied the impact of noise existing in the software repository or provided effective ways to reduce the noise. But they did not directly address the defect localization problem as studied in our paper.

In recent years, Zhou et al. have used the VSM to represent the texts and taken the length of source files into consideration combining the similar bugs to revise the ranking list. A dedicated tool, i.e. BugLocator\(^b\) is implemented to facilitate the approach [1]. Many other non-textual attributes are used to enhance the performance, such as version history [3]. Saha et al. found that the code construct is important for bug localization, so they proposed a structure information retrieval approach [4]. Wang et al. combined the above three discoveries to increase the results [5]. Moreover, Ye et al. have used the domain knowledge to cover all accessible features to enhance the IR-based bug location technique [6]. In order to help the developers pick an effectiveness approach proposed in the literature, Le et al. presented the approach APRILE to predict the effectiveness of the localization tools [23]. The aforementioned bug localization efforts took available software metrics into account and paid more attention to the relationship between bug reports, but they neglected the POS of bug reports and the invocation relationship among source files. Our work complements with the consideration from this aspect.

Besides spectrum and IR-based defect localization, some other analysis and tracking methods have been applied to bug localization, such as [24, 25]. In [24], DeMott et al. enhanced the code-coverage based fault localization by incorporating input data tainting and tracking using a light-weight binary instrumentation technique. However, their approach mainly targets at a specific class of software bugs, i.e. memory corruption related errors. In [25], Zhang et al. observed that not all statements in a static slice are equally likely to affect another statement and proposed a prioritized static-slicing based technique to improve the fault localization. The work is solely based on static analysis, without considering the information from bug reports.

3. Background

3.1. Basic ranking framework

IR is a process to find the contents in a database related to the input queries. The matching result is not unique, but consists of several objects with different degrees of relevance, forming a ranking list [26]. The basic idea of defect localization using IR is to compute the similarity between textual information of a given bug report and the source code of the related project. It takes the summary and description parts of a

\(^b\)https://code.google.com/archive/p/bugcenter/.
bug report as a query, the source files as documents, and ranks the relevance depending on similarity scores.

To identify relevant defect source files, the textual part of bug reports and source code are typically transformed into a suitable representation respecting a specific model. In our approach, we use the VSM (a.k.a. Term Vector Model) [27] which represents a query or a file as a vector of index terms.

In order to transform texts into word vectors more efficiently, we need to preprocess the textual information. The traditional text preprocessing involves three steps: first, we replace all non-alphanumeric symbols with white spaces, and split texts of bug reports into a stream of terms by white spaces. Second, meaningless or frequently used terms called stop word, such as propositions, conjunctions and articles, are all removed. Usually, the stop word list of the source code is totally different from natural language documents and is always composed of particular words relying on programming languages. Third, all remaining words are transformed into their basic form by the Poster Stemming Algorithm, which can normalize the terms with different forms.

After preprocessing, we take the rest terms of bug reports as index terms to build vector spaces which represent each bug report and source file as vectors. The weight of an index term in a bug report is based on its Token Frequency (TF) in the bug report and its Inverse Document Frequency (IDF) in the whole bug reports. The same goes for the weight of an index term in a source file. We assume that the smaller the angle of two vectors is, the closer the two documents represented by the two vectors are [28].

3.2. POS tagging

POS tagging is the process of marking up a term as a particular part of speech based on its context, such as nouns, verbs, adjectives, and adverbs, etc. Because a term can represent more than one part of speech at different sentences, and some parts of speech are complex or indistinct, it becomes difficult to perform the process exactly. However, research has improved the accuracy of POS tagging, giving rise to various effective POS taggers such as TreeTagger, TnT (based on the Hidden Markov model), Stanford tagger [29–31]. State of the art taggers highlight accuracy of circa 93% compared to the human’s tagging results.

In recent years, researchers have tried to help developers in program comprehension and maintenance by analyzing textual information in software artifacts [32]. The IR-based framework is widely used and the POS tagging technique has demonstrated to be effective for improving the performance [33, 34]. Tian et al. have investigated the effectiveness of seven POS taggers on sampled bug reports; the Stanford POS tagger and TreeTagger achieved the highest accuracy up to 90.5% [35].

In our study, the textual information of bug reports is composed in natural language. As mentioned before, we have discovered that the noun-based terms are more important for bug localization. Therefore, we have made use of POS tagging
techniques to label the terms and adjusted the weight of the terms in vector transforming accordingly.

3.3. Evaluation metrics

Three metrics are used to measure the performance of our approach.

(1) Top $N$ is the number of buggy files localized in top $N$ ($N = 1, 5, 10$) of the returned results. A bug is related to many buggy files and if one of the buggy files is ranked in top $N$ of the returned list, we consider the bug to be located in top $N$. Moreover, the higher the metric value is, the better our approach performs.

(2) MRR (Mean Reciprocal Rank) [36] is a statistic measure for evaluating the process that produces a sample of the ranking list to all queries. The reciprocal rank of a list is the multiplicative inverse of the rank of the first correct answer. The mean reciprocal rank is the average of the reciprocal ranks for all queries $Q$:

$$MRR = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{\text{rank}_i}.$$  (1)

where $\text{rank}_i$ is the rank of the first correct recommended file to bug report $i$ and $|Q|$ is the number of all bug reports.

(3) MAP (Mean Average Precision) [26] is a global measurement for all of the ranking lists. It takes all of the rankings of the buggy files into account. There are possibly several relevant source code files corresponding to a bug report, the Average Precision ($AP$) for a bug report $r$ can be calculated as:

$$AP_r = \frac{\sum_{k=1}^{|S|} P(k) \times \text{pos}(k)}{\text{Numbers of Defective Files}},$$  (2)

where $|S|$ is the number of source files, and $\text{pos}(k)$ is the indicator representing whether or not the file at rank $k$ is a real defect. $P(k)$ is the precision at the given cut-off rank $k$. $MAP$ is the mean of the average precision values for all bug reports.

For example, ZXing\(^c\) project contains two bug reports #383 and #492. Assume that the bug report #383 results from two buggy files and the final rankings of these files by our approach are 3 and 8, respectively. The bug report #492 relates to five buggy files and the final rankings of these files by our approach are 1, 37, 101, 154 and 244. Thus, the Top 1 for the bug reports #383 and #492 are 3 and 1, respectively. For MRR, the value can be calculated as:

$$MRR = \frac{1}{2} \sum_{i=1}^{2} \frac{1}{\text{rank}_i} = \frac{1}{2} \times \left( \frac{1}{3} + 1 \right) = \frac{2}{3}.$$  (3)

\(^c\)https://github.com/zxing/zxing.
The Average Precision (AP) for the first Zxing Bug Report #383 can be computed as:

\[
AP_{\#383} = \frac{\sum_{k=1}^{391} P(k) \times pos(k)}{\text{Numbers of Defective Files}} = \frac{1}{2} \times \left( \frac{1}{3} + \frac{1}{4} \right) = 0.29.
\] (4)

Similarly,

\[
AP_{\#492} = \frac{1}{5} \times \left( 1 + \frac{1}{37} + \frac{1}{101} + \frac{1}{154} + \frac{1}{244} \right) = 0.23.
\] (5)

Based on the above values, we then can get that the mean average precision (MAP) for Project Zxing is 0.26.

These metrics are commonly used in the IR research. Particularly, many bug localization studies adopt such metrics to evaluate the performance of their approaches on given data sets [1, 4, 8, 37].

4. Approach

Our approach consists of two interconnecting modules and a parameter \textit{opt}. The two modules are:

- \textit{Module 1} is a revised VSM combining with POS oriented weighting method. A ranking list for a certain bug report will be produced. In this module, we use a revised VSM to represent the bug report and index the source code files for similarity calculation. The proposed weighting method was applied automatically to adjust the weight of each term based on its tag. We note that the way of filtering the source code is determined by the parameter \textit{opt}.

- \textit{Module 2} is based on the results of \textit{module 1}. We use the invocation relationship to further augment the accuracy of the results. In this module, we will search the summary and description parts of a bug report for the class-name terms. If the corresponding source files of the class have been ranked high in \textit{module 1}, their invoking files will be raised accordingly in the ranking lists.

The parameter \textit{opt} is a Boolean indicator of our adaptive recommendation depending on the developers’ context. If the value of \textit{opt} is set to be true, it means developers want a single decisive, i.e. the most probable file to this bug report; if its value is \textit{false}, it indicates a list of \textit{n} files would be provided.

Our approach leverages natural language processing techniques to adjust the weights of terms depending on their POS, and takes advantage of heuristics in bug reports to balance the importance of summary and description. Moreover, the invocation relationship between source files can be generated from program comprehension techniques based on static analysis. Figure 2 gives an overview of our approach. The details will be elaborated below.
In this module, the similarity scores between the new bug report and the candidate source files are calculated, and then an initial ranking list is produced. It is a prerequisite that the POS is tagged before the text preprocessing. Namely, the inputs to the POS tagger are all complete sentences. We use the state-of-the-art POS tagger Stanford-Postagger\(^d\) to mark all of the terms of the bug reports.

Figure 3 illustrates the tagging results for the summary of AspectJ (Bug ID: 29769). The output includes words of the sentences and their parts of speech which have been defined in the English tagging model of Stanford-Postagger. We can see that the words “Ajde”, “AspectJ”, “compiler” and “options” are all noun terms. We duplicate the terms marked as “NN (noun, singular or uncountable)”, “NNS (noun, plural)”, “NNP (proper noun, singular)” and “NNPS (proper noun, plural)” three times and other terms twice to increase the weights of noun-based terms. Moreover, this weighting strategy would not increase the dimension of VSM and thus it need not keep the markings until the calculation step. We aim to highlight the nouns comparing to others, thus the weights of the terms with all noun types increase without any difference.

The descriptive parts, i.e. description and summary, of a bug report are regarded as a query, but the significance of these two parts is different [38]. In order to highlight the summary, we follow the heuristics from [39] to increase its terms’ frequency twice of that of the description. For source files, we filter the source code

\(^d\)http://nlp.stanford.edu/software/tagger.shtml.
before preprocessing, and set the Boolean parameter \( opt \) to determine what kind of files are recommended. Because the empirical cases studied in our paper are programmed in Java, we leverage API of Eclipse JDT, namely \textit{ASTParser}, to parse the source code. \textit{ASTParser} can analyze the main components of a source file, such as classes, methods, statements and annotations. The source code can be parsed as a compilation unit. By calling the methods of this API, we can remove some useless elements in the source code. In our approach, all annotations of source code are filtered out. Moreover, if the value of the parameter \( opt \) is set to be true, only class names and method names of the source files will be reserved. We take the filtered source code files as documents and the weight-processed bug reports as queries. In this way, we can build a VSM to represent both texts based on the index terms of bug reports and source code. The weight \( w_{t,d} \) of a term \( t \) in a document \( d \) is computed based on the term frequency (\( tf \)) and the inverse document frequency (\( idf \)), which are defined as follows:

\[
    w_{t,d} = tf_{t,d} \times idf_{t},
\]

where \( tf_{t,d} \) and \( idf_{t} \) are computed as:

\[
    tf_{t,d} = \frac{f_{t,d}}{t_d},
\]

\[
    idf_{t} = \log \left( \frac{n_d}{n_t} \right).
\]

Here, \( f_{t,d} \) is the number of the occurrences of term \( t \) in document \( d \) and \( t_d \) is the total number of terms document \( d \) includes. \( n_d \) refers to the number of all documents and \( n_t \) is the number of documents containing term \( t \). Thus, \( w_{t,d} \) is high if the occurrence frequency of term \( t \) in document \( d \) is high and the term \( t \) seldom exists in other documents. Obviously, if a term appears five times in a document, its importance

---

Fig. 3. The tagging results.
should not be five times compared to the ones appearing once [26]. In view of this point, we use the logarithm variant to adjust $t_{ft,d}$ [40]:

$$t_{ft,d} = \log(f_{t,d}) + 1. \quad (9)$$

The similarity score between a query and a document is the cosine similarity calculated by their vector representations computed above:

$$Sim_{t,d} = \frac{\sum_{i=1}^{m} w_{t_i,q} \times w_{t_i,d}}{\sqrt{\sum_{i=1}^{m} w_{t_i,q}^2} \times \sqrt{\sum_{i=1}^{m} w_{t_i,d}^2}}, \quad (10)$$

where $m$ is the dimension of the two vectors and $w_{t_i,q}$ (respectively $w_{t_i,d}$) represents the weight of term $t_i$ in query $q$ (respectively document $d$).

Previous work has shown that large source code files have a high possibility to be defective [41, 42]. Our approach also takes file length into account and sets a coefficient $\text{lens}$ based on file length to adjust the similarity scores. The range of lengths of source code files is usually large and we must map the lengths to an interval, namely $(0.5, 1.0)$. To this end, we first compute the average length $\text{avg}$ of all source files and then calculate the standard deviation $\text{sd}$ as:

$$\text{sd} = \sqrt{\frac{\sum_{i=1}^{n} (l_i - \text{avg})^2}{n}}, \quad (11)$$

where $n$ is the total number of source files. $l_i$ is the length of source code file $i$. We have an interval $(\text{low}, \text{high})$ which is defined as:

$$\text{low} = \text{avg} - 3 \times \text{sd}, \quad \text{high} = \text{avg} + 3 \times \text{sd} \quad (12)$$

and the length $l_i$ of the source file will be normalized as $\text{norm}$:

$$\text{norm} = \begin{cases} 
0.5, & l_i \leq \text{low}, \\
6.0 \times \frac{(l_i - \text{low})}{\text{high} - \text{low}}, & \text{low} < l_i < \text{high}, \\
1.0, & l_i \geq \text{high}.
\end{cases} \quad (13)$$

The coefficient $\text{lens}$ is computed as:

$$\text{lens} = \frac{e^{\text{norm}}}{1 + e^{\text{norm}}}. \quad (16)$$

Finally, the similarity score between a bug report (the query) and a source code file (the document) can be calculated as:

$$Sim_{t,d} = \text{lens} \times \frac{\sum_{i=1}^{m} w_{t_i,q} \times w_{t_i,d}}{\sqrt{\sum_{i=1}^{m} w_{t_i,q}^2} \times \sqrt{\sum_{i=1}^{m} w_{t_i,d}^2}}. \quad (17)$$

We then obtain all of the similarity scores of source files and bug report and thus form a ranking list according to the scores.
4.2. Module 2 — Invocation-based calibration

As usual, the summary only depicts one obvious defect file and seldom contains methods of other buggy files, resulting in poor performance of locating the other hidden buggy files. In order to increase the ranking of all buggy files and improve the overall performance, we also leverage the invocation information between high-ranked buggy files to increase scores of the other buggy files.

The textual information of a bug report has been processed already and may include one or more class-name terms. We define the source files corresponding to the class-name terms as hitting files, and the hitting file which ranks the highest on the initial ranking list produced by module 1 as hf. We hypothesize that the hf has the highest possibility to be the defective source file. Figure 4 shows the detailed processing of the invoking method. First, we extract all class-name terms of a new bug report r and collect the hitting files corresponding to these terms. Next, we select the highest ranking source file hf of the hitting files. We then review the invocation corpus to find the invocation files. At last, the final score ($F_{Score_r,inf}$) of the invoking file inf in module 2 is calibrated as follows:

$$F_{Score_r,inf} = a \times Sim_{r,hf} + (1 - a) \times Sim_{r,inf},$$

Fig. 4. The detail of Module 2: Invoking method.
where $Sim_{r,hf}$ is the similarity score between the highest scored file $hf$ of the hitting file and the bug report $r$, and $Sim_{r,inf}$ is the similarity score between the file $inf$ invoked by $hf$ and the bug report $r$. $a$ is the parameter of the formula which is different in various projects to further adjust the weight of $Sim_{r,inf}$.

The most important part of module 2 is the invocation corpus which is automatically produced in advance by programs based on API of Call Hierarchy in Eclipse. The structure of the invocation corpus of a project is similar to that of its source code. In order to find the invocation files of $hf$, we need to locate the class folder by utilizing the package name of the $hf$. There is a list of method folders under the class folder and there are two main folders in these method folders, namely callers and callees which consist of the invocation information of $hf$. Then, by reading the files of these two folders and extracting the invocation information, we can collect the invocation files of $hf$. The invocation corpus is calculated once and stored as a repository for future use. Module 2 of our approach aims to improve the performance for bug localization by adjusting the similarity scores of invoking files. This invocation method can be combined with most IR-based bug localization approaches, including BugLocator. Of course, the coefficients combining the invocation method and the other two original parts of BugLocator should be updated.

4.3. Adaptive strategy

As mentioned before, Top 1 recommendation and other Top $N$ (e.g. $N = 5, 10$) recommendations use different identification strategies. We have considered two common situations. If the developers only need a decisive file, the accuracy of Top 1 will get a preferential treatment. In this situation, we remove all of the elements of the source files except for the class names and method names. Otherwise, the developers need $N$ (for example, $N = 5, 10$) candidate files, and thus the overall performance of Top $N$ ($N = 5, 10$) must be considered and we find that keeping all of the essential elements of the source files except annotation is better.

On top of that, we propose an adaptive approach which can maximize the performance of bug localization recommendation. Our adaptive strategy is based on the analysis of properties in source code files and bug reports, which is implemented by a parameter $opt$ set by developers. The parameter controls both the element filtering of source code files and the output of the overall approach shown in Fig. 2. When $opt$ is set to be true, it means developers want a decisive file to the bug, and other elements of source files except for class names and method names must be removed before text preprocessing. The output of our recommendation is then a single file. Otherwise, it means that a list of $N$ ($N = 5, 10$) files would be provided. The output of the our recommendation is then $N$ candidate files accordingly.

5. Experiments

To evaluate our approach, we conduct an empirical study and use the same four cases as in [1], i.e. AspectJ, Eclipse, SWT and ZXing. To demonstrate an even
broader applicability, we also include another two cases, i.e. Birt and Tomcat. These two extracted projects are also intensively studied in the related bug localization work, such as [6]. The information of the dataset is given in Table 1. We compare our approach with the rVSM model of BugLocator ($\alpha = 0$). BugLocator is an IR-based bug localization approach proposed in [1]. It takes the length of files into consideration and applies similar bug reports which have been localized to predict the current bug report. BugLocator consists of two main parts, i.e. ranking based on source code files (similar to our module 1 excluding POS) and ranking based on similar bugs (our module 2 based on the invocation between source files). The parameter $\alpha$ is the coefficient combining the scores obtained from querying source code files (rVSMscore) and from similar bug analysis (SimiScore). Namely, when $\alpha$ is set to be 0, BugLocator ranks based on rVSMscore solely.

Our experiments are conducted on a PC with an Intel i7-4790 3.6 GHz CPU and 32 G RAM running Windows 7 64-bit Operating System, and JDK version is 64-bit 1.8.0-65. Table 2 depicts the results achieved by our approach for all of the six projects. If the value of $opt$ is set to be true, about 114 AspecJ bugs (39.86%), 946 Eclipse bugs (30.76%), 46 SWT bugs (46.94%), 11 ZXing bugs (55%), 916 Birt bugs (21.99%) and 331 Tomcat bugs (38.90%) are successfully located and their fixed files can be found at the Top 1 in recommendation. If the value of $opt$ is set to be false, our approach can locate 76 AspecJ bugs (26.57%), 912 Eclipse bugs (29.66%), 39 SWT bugs (39.79%), 6 ZXing bugs (30%), 382 Birt bugs (9.17%) and 287 Tomcat bugs (33.73%) whose fixed files are at the Top 1, 135 AspecJ bugs (47.20%), 1571 Eclipse bugs (51.09%), 72 SWT bugs (73.47%), 13 ZXing bugs (65%), 851 Birt bugs (20.43%) and 489 Tomcat bugs (57.46%) whose fixed files are at the Top 5 and 168 AspecJ bugs (58.74%), 1854 Eclipse bugs (60.29%), 81 SWT bugs (82.65%), 13 ZXing bugs (65%), 1138 Birt bugs (27.32%) and 554 Tomcat bugs (65.10%) whose fixed files are at the Top 10. Besides, the results of $MRR$ and $MAP$ when $opt$ is true are better than the ones when $opt$ is false in all of the cases but Eclipse, because the result of Top 1 contributes more to the performance of $MRR$ and $MAP$ than the results of Top 5 and Top 10, while in Eclipse the difference between the Top 1 recommendation is very marginal.

Method 1 defines the process of locating the bugs in our approach when $opt$’s value is true and Method 2 represents another process of locating the bugs when $opt$’s value
is false. Method 1 takes advantage of the localized bug reports and filters out more noisy data, contributing more to the accuracy of Top 1 recommendation. From the results of Top 1 for the six projects with the two methods, we have observed that the results of Top 1 with Method 1 are better than the results of Top 1 with Method 2 for all of the six projects which confirms the above idea. With the increasing scale of bug reports, the localized bug reports also get increased and play a dominant role in bug localization leading to the better performance of Top 1.

Because our approach has filtered the source code in the beginning, particularly when opt is true, module 1 seems more time-saving compared to BugLocator without similar bugs module. Table 3 illustrates the execution time of rVSM model and module 1 of our approach. The execution time of BugLocator (α = 0) for AspectJ,
Eclipse, SWT, ZXing, Birt and Tomcat is 56 s, 57 min, 6 s, 3 s and 85 s, respectively. The execution time of the module 1 of our approach is 49 s, 9 min, 12 s, 6 s and 40 s, respectively. Although the time cost of our approach for SWT and ZXing is higher compared to that of BugLocator, from Table 3, we can find the larger the project is, the better advantage our approach can achieve. Figure 5 pictorially illustrates the execution time comparison of the two approaches. Because the execution time of the six projects is not at the same level, we set the execution time of each project using BugLocator as the unit time 1 and represent the time cost of our approach as the proportion of the execution time of BugLocator. We can observe that the module 1 relatively decreases the execution time and is more efficient. Moreover, the larger the source code and bug reports are, the more time-saving the module 1 is.

In our approach, we have made use of the saving time to execute the module 2 which is considerably time-consuming. It is generally known that extracting the invocation relationship of a large project like Eclipse is very complex and thus costs much time. Although our approach does not need to obtain the invocation relationship of all source files, it does need to review thousands of highest scored source files \( h_f \) to get the invoking files. We emphasize that, in our approach, the calculation only needs to be conducted once and offline, and can be used in the future, since the invocation relationship is stored as a repository.

As mentioned before, BugLocator contains two modules. If \( \alpha \) is greater than 0, it also analyzes similar bug reports, which inevitably brings additional burden of calculation, and certainly is more time-consuming. We have compared the performance of our approach to BugLocator without similar bugs because we try to emphasize the importance of POS and invocation relationship between source files and do not combine the similar bugs. Table 4 compares the accuracy of our approach with BugLocator. As we can see, the performance of both methods of our approach is better than BugLocator without using similar bugs.
When \( opt \) is set to be \textit{true}, our approach recommends one file with the highest similarity score to the developers and actually the accuracy of recommended file is sharply high. All of the results have a considerable enhancement. For example, the accuracy of \textit{Top 1} of this method for Aspect\( J \) almost improves twice. The performance of \textit{Method 1} are 39.86\% for Aspect\( J \) compared to 22.73\% of rVSM, 30.76\% for Eclipse compared to 24.36\%, 46.94\% for SWT compared to 31.63\%, 55\% for ZXing compared to 40\%, 21.99\% for Birt compared to 7.97\% and 38.90\% for Tomcat compared to 33.37\%. Although this method just provides one file, the statistics of \textit{MRR} and \textit{MAP} are based on the ranking lists \textit{Method 1} produces inside. Although it
sacrifices the performance of Top 5 and Top 10 in a certain degree, the metric values of MRR and MAP are also higher than BugLocator without using similar bugs, which implies the benefits of our approach.

When opt is set to be false, our approach recommends n candidate files based on the ranking list of a bug report to the developers. Our approach increases the precision of defect files in top N (N = 5, 10) effectively. The performance enhancement is about 3.84% in Top 1, 6.29% in Top 5 and 3.15% in Top 10 for AspectJ, about 5.30% in Top 1, 4.94% in Top 5 and 4.39% in Top 10 for Eclipse, about 8.16% in Top 1, 8.16% in Top 5 and 5.10% in Top 10 for SWT, about 10% in Top 5 for ZXing, about 1.20% in Top 1, 2.98% in Top 5 and 3.24% in Top 10 for Birt and about 0.36% in Top 1, 2.58% in Top 5 and 1.18% in Top 10 for Tomcat. From the results, it is interesting to observe that our approach improves the performance most in Top 5 on average.

To further explain the performance of the two selective methods in our approach, we extend N to cover more value options, i.e. from 1 to 10. In this experiment, Figure 6(a) shows the performance of AspectJ with 286 bug reports from Top 1 to Top 10. AspectJ-True means Method 1 and AspectJ-False means Method 2. It is obvious that the performance of Method 1 increases sharply at Top 1 and then slows down. For Method 2, the results increase quickly from Top 1 to Top 10 at almost the same speed and get better after Top 5 than Method 1.

For the Eclipse project with 3075 bug reports, only the Top 1 of Method 1 is still better than the Top 1 of Method 2. The results of Method 1 from Top 2 to Top 10 are all worse than that of Method 2. The performance comparison between the two methods for the Eclipse project is shown in Fig. 6(b). As we can see, only the Top 1 of Method 1 is better even though the scale of bug reports increases from 286 of AspectJ to 3075 of Eclipse. This is also the case for the SWT project, ZXing project and Tomcat project, illustrated by Figs. 6(c), 6(d) and 6(f), respectively. However, Birt
Fig. 6. (Continued)
project exhibits different properties. From Fig. 6(e), we can observe that the performance of Method 1 is continuously better than Method 2, although the difference between them is decreasing. The fact indicates a converging trend of the two methods. The general suggestion is that, if developers want a recommended file, with our approach they can make use of Method 1. If they want $N$ ($N = 5, 10$) recommended files instead, they should make use of Method 2.

6. Threats to Validity

In this section, we discuss the possible threats to the validity in our approach, mainly the concerns of data validity and invocation validity.
Data Validity. The experimental dataset we used are all programmed by Java and the keywords of bug reports are mainly class names or method names which make the VSM model more effective than other IR-based models. The performance of Top 1 gets better when we only reserve class names and method names in source code and the results of Top 5, Top 10 decrease at this situation and we can get the rule that class names and method names contribute to the results of Top 1. But we just used the dataset of Zhou et al. [1] and two others to assure the fair comparison. Thus, whether or not this heuristic fits all of the Java projects still requires further studied to confirm.

Invocation Validity. We generate the invocation corpus by using the JDT’s plug-in called Call Hierarchy [43, 44] and search the invocation files from the corpus afterwards. Although the call graph of the projects we use in our experiments is of large scale, especially for Eclipse, and the generation with the large repository can take an additional amount of time, the invocation corpus can be reused once it was produced which seems to be more time-saving in long terms. Moreover, due to the characteristic of the source code, we cannot say that the invocation corpus contains all the invocation files of a particular file. Compared to the simple string-based searching method used in [9], the invocation corpus can avoid re-calculating each time.

7. Conclusion and Future Work

In software life cycles, maintenance is the most time-consuming and highly cost phase. An in-time bug fixing is of crucial importance. To mitigate the work of software developers, in this paper, we propose an adaptive approach to recommending potential defective source files given a certain bug report. We take advantages of POS tagging techniques and the logical invocation relationship between source files and present an automatic weighting method to further improve the performance. As far as we know, this is the first work considering the underlying POS features in bug reports for bug localization. The evaluation results on six large open-source projects demonstrate the feasibility of our adaptive approach and also indicate better performance compared to the baseline work, i.e. BugLocator.

In the future, we plan to integrate more features of program to our approach, such as similar bugs, version history and dynamic information. The aim is to propose a more adaptive approach for more complex user demands. More technically, the module 2 of the our approach will be refined to decrease the number of noisy files, which may produce further enhancement. Moreover, our approach will be expanded to utilize other kinds of dataset, such as bug reports of commercial projects and unresolved bug reports, to demonstrate a broader applicability.
