Abstract

XML repositories are now a widespread means for storing and exchanging information on the Web. As these repositories become increasingly used in dynamic applications such as e-commerce, there is a rapidly growing need for a mechanism to incorporate reactive functionality in an XML setting. Event-condition-action (ECA) rules are a technology from active databases and are a natural method for supporting such functionality. ECA rules can be used for activities such as automatically enforcing document constraints, maintaining repository statistics, and facilitating publish/subscribe applications. An important question associated with the use of a ECA rules is how to statically predict their run-time behaviour. In this paper, we define a language for ECA rules on XML repositories. We then investigate methods for analysing the behaviour of a set of ECA rules, a task which has added complexity in this XML setting compared with conventional active databases.

Keywords: Event-condition-action rules, XML, XML repositories, reactive functionality, rule analysis.

1 Introduction

XML is becoming a dominant standard for storing and exchanging information. With its increasing use in areas such as data warehousing and e-commerce [13, 14, 18, 22, 28], there is a rapidly growing need for rule-based technology to support reactive functionality on XML repositories. *Event-condition-action (ECA)* rules are a natural candidate to support such functionality. In contrast to implementing reactive functionality directly within a programming language such as Java, ECA rules have a high level, declarative syntax and are thus more easily analysed. Furthermore, many commercial and research systems based on ECA rules have been successfully built and deployed, and thus their implementation within system architectures is well-understood.

ECA rules automatically perform actions in response to events provided stated conditions hold. They are used in conventional data warehouses for incremental maintenance of materialised views, for validation and cleansing of the input data streams, and for maintaining audit trails of the data. By analogy, ECA rules can also be used as an integrating technology for providing this kind of reactive functionality on XML repositories. They can also be used for checking key and other constraints on XML documents, and for performing automatic repairs when violations are detected. For a 'push' type environment, they are a mechanism for automatically broadcasting information to subscribers as the contents of relevant documents change. They can also be employed as a flexible means for maintaining statistics about document and web site usage and behaviour. In this paper, we present a language in which ECA rules on XML can be defined.

ECA rules have been used in many settings, including active databases [26, 29], workflow management, network management, personalisation and publish/subscribe technology [3, 13, 14, 17, 27], and specifying and implementing business processes [2, 16, 22]. However, one of the key recurring themes regarding the successful deployment of ECA rules is the need for techniques and tools for analysing their behaviour [15, 23]. When multiple ECA rules are defined within a system, their interactions can be

1

difficult to analyse, since the execution of one rule may cause an event which triggers another rule or set of rules. These rules may in turn trigger further rules and there is indeed the potential for an infinite cascade of rule firings to occur. Thus, the second part of this paper explores techniques for analysing the behaviour of a set of ECA rules defined in our language.

Other ECA rule languages for XML have been proposed in [13, 14, 22] but none of these focus on analysing the behaviour of the ECA rules. It is proposed in [13] that analysis techniques developed for conventional active databases can be applied in an XML setting too, but details are not given.

A more recent paper [12] also defines an active rule language for XML, but is not concerned with rule analysis. The rule syntax it describes is similar to the one we define here, the rule format being based on the definition of triggers in SQL3. Its rule execution semantics is rather different from the model we adopt, however. Generally speaking, insertions and deletions of XML data (so-called *bulk* statements) may involve document fragments of unbounded size. [12] describes a semantics whereby each (top-level) update is decomposed into a sequence of smaller updates (which depend on the contents of the fragment being inserted/deleted) and then trigger execution is interleaved with the execution of these smaller updates. In contrast, we treat each top-level update as atomic and trigger execution is invoked only after completion of the top-level update. In general, these semantics may produce different results for the same top-level update and it is a question of future research to determine their respective suitability in different applications.

In an earlier paper [7] we described some initial proposals for analysis, and also optimisation, of XML ECA rules. The language we discussed there was less expressive then the language we propose here in that it did not allow disjunction or negation in rule conditions. Moreover, here we examine more deeply the triggering and activation relationships between rules and have derive more precise tests for determining both of these relationships than the tests we described in [7].

2   The ECA Rule Language

An *XML database* consists of a set of XML documents. *Event-condition-action (ECA)* rules on XML databases take the following form:

$$\begin{aligned} &\texttt{on} \;\; event \\ &\texttt{if} \;\; condition \\ &\texttt{do} \;\; actions \end{aligned}$$

Rather than introducing yet another query language for XML, we use the XPath [32] and XQuery [33] languages to specify events, conditions and actions within our ECA rules. XPath is used in a number of W3C recommendations, such as XPointer, XSLT and XQuery itself, for selecting and matching parts of XML documents and so is well-suited to the requirements of ECA rules. XQuery is used in our ECA rules only where there is a need to be able to construct new fragments of XML. We define each of the components of our ECA rule language below, give some example rules, and describe the rule execution semantics.

2.1   Rule Events

The *event* part of an ECA rule is an expression of the form

INSERT *e*

or

DELETE *e*

where *e* is a *simple XPath expression* (defined in Section 2.4 below) which evaluates to a set of nodes. The rule is said to be *triggered* if this set of nodes includes any node in a new sub-document, in the case of an insertion, or in a deleted sub-document, in the case of a deletion.

The system-defined variable $delta is available for use within the condition and actions parts of the rule (see below), and its set of instantiations is the set of new or deleted nodes returned by *e*.

2.2 Rule Conditions

The *condition* part of an ECA rule is either the constant `TRUE`, or one or more simple XPath expressions connected by the boolean connectives `and`, `or`, `not`.

The condition part of an ECA rule is evaluated on each XML document in the database which has been changed by an event of the form specified in the rule's event part. If the condition references the system-defined `$delta` variable, it is evaluated once for each instantiation of `$delta` for each document. Otherwise, the condition is evaluated just once for each document.

2.3 Rule Actions

The *actions* part of an ECA rule is a sequence of one or more actions:

$$action_1; \ldots; action_n$$

These actions are executed on each XML document which has been been changed by an event of the form specified in the rule's event part and for which the rule's condition query evaluates to True — we call this set of documents the rule's set of *candidate documents*.

An ECA rule is said to *fire* if its set of candidate documents is non-empty.

Each $action_i$ above is an expression of the form

$$\texttt{INSERT } r \texttt{ BELOW } e \texttt{ [BEFORE|AFTER } q]$$

or

$$\texttt{DELETE } e$$

where r is a *simple XQuery expression*, e is a *simple XPath expression* and q is either the constant `TRUE` or an *XPath qualifier* — see Sections 2.4 and 2.5 below for definitions of the italicised terms.

In an `INSERT` action, the expression e specifies the set of nodes, N, immediately below which new sub-document(s) will be inserted. These sub-documents are specified by the expression r[1]. If e or r references the `$delta` variable then one sub-document is constructed for each instantiation of `$delta` for which the rule's condition query evaluates to True. If neither e nor r references `$delta` then a single sub-document is constructed[2].

q is an optional XPath qualifier which is evaluated on each child of each node $n \in N$. For insertions of the form `AFTER` q, the new sub-document(s) are inserted after the last sibling for which q is True, while for insertions of the form `BEFORE` q, the new sub-document(s) are inserted before the first sibling for which q is True. The order in which new sub-documents are inserted is non-deterministic.

In a `DELETE` action, expression e specifies the set of nodes which will be deleted (together with their sub-documents). Again, e may reference the `$delta` variable.

Example 1 Consider an XML database consisting of two documents, `s.xml` and `p.xml`. The document `s.xml` contains information on stores, including which products are sold in each store:

```
<stores>
  <store id="s1">
    <location>...</location>
    <manager>...</manager>
    <product id="p1"/>
    <product id="p2"/>
    ...
  </store>
  ...
</stores>
```

---

[1] We observe that using the phrase `BELOW` e to indicate where the update should happen is significant. Without it the placement of new sub-documents would be restricted to occurring only at the root node of documents.

[2] Thus, both *document-level* and *instance-level* triggering are supported in our ECA rule language. If there is no occurrence of the `$delta` variable in a rule action, the action is executed at most once on each document each time the rule fires — this is document-level triggering. If there is an occurrence of `$delta` in an action part, the action is executed once for each possible instantiation of `$delta` on each document — this is instance-level triggering.

The document `p.xml` holds information on each product, including which stores sell each product:

```
<products>
  <product id="p1">
    <name>...</name>
    <category>...</category>
    <price>...</price>
    <store id="s1"/>
    <store id="s2"/>
    ...
  </product>
  ...
</products>
```

The following ECA rule updates the `p.xml` document whenever one or more products are added below an existing store in `s.xml`:

```
on INSERT document('s.xml')/stores/store/product
if not(document('p.xml')/products/
   product[@id=$delta/@id]/store[@id=$delta/../@id])
do INSERT <store id='{$delta/../@id}'/>
          BELOW document('p.xml')/products/
                product[@id=$delta/@id] AFTER TRUE
```

Here, the system-defined `$delta` variable is bound to the newly inserted `product` nodes detected by the event part of the rule. The rule's condition checks that the store which is the parent of the inserted products in `s.xml` is not already a child of those products in `p.xml`. The action then adds the store as a child of those products in `p.xml`.

In a symmetrical way, the following ECA rule updates the `s.xml` document whenever one or more stores are added below an existing product in `p.xml`:

```
on INSERT document('p.xml')/products/product/store
if not(document('s.xml')/stores/
   store[@id=$delta/@id]/product[@id=$delta/../@id])
do INSERT <product id='{$delta/../@id}'/>
          BELOW document('s.xml')/stores/
                store[@id=$delta/@id] AFTER TRUE
```

The two rules ensure that the information in the two documents is kept mutually consistent. ∎

Example 2 This example is taken from [1] which discusses view updates on semi-structured data. The XML database consists of two documents, `g.xml` and `m.xml`. `g.xml` contains a restaurant guide, with information about restaurants, including the entrees they serve, and the ingredients of each entree:

```
<guide>
  <restaurant>
    <name>Thai City</name>
    <rating>5</rating>
  </restaurant>
  <restaurant>
    <name>Baghdad Cafe</name>
    <rating>9</rating>
    <entree>
      <name>Beef Stew</name>
      <ingredient>Mushroom</ingredient>
    </entree>
    <entree>
```

```
        <ingredient>Tomato</ingredient>
      </entree>
    </restaurant>
    <restaurant>
      <name>Eats</name>
      <rating>Four stars</rating>
      <entree>
        <ingredient>Tomato</ingredient>
      </entree>
      <entree>
        <name>Cheeseburger Club</name>
        <ingredient>Cheese</ingredient>
        <ingredient>Beef</ingredient>
      </entree>
    </restaurant>
    ...
</guide>
```

The document m.xml is a view derived from g.xml, and contains a list of those entrees at the Baghdad Cafe where one of the ingredients is Mushroom:

```
<entrees>
  <entree>
    <name>Beef Stew</name>
    <ingredient>Mushroom</ingredient>
  </entree>
</entrees>
```

Suppose now an ingredient element with value Mushroom is added to the second (unnamed) entree of the Baghdad Cafe in g.xml. The following ECA rule performs the view maintenance of m.xml:

```
on INSERT document('g.xml')/guide/restaurant/
           entree/ingredient
if $delta[.='Mushroom'] and
   $delta/../..[name='Baghdad Cafe']
do INSERT $delta/.. BELOW document('m.xml')/entrees
   AFTER TRUE
```

The resulting m.xml document is:

```
<entrees>
  <entree>
    <name>Beef Stew</name>
    <ingredient>Mushroom</ingredient>
  </entree>
  <entree>
    <ingredient>Tomato</ingredient>
    <ingredient>Mushroom</ingredient>
  </entree>
</entrees>
```

Note that inserting $delta/.. results in the complete entree being inserted, while AFTER TRUE causes it to be inserted after the last child of entrees. ∎

2.4 Simple XPath Expressions

The XPath and XQuery expressions appearing in our ECA rules are restrictions of the full XPath [32] and XQuery [33] languages, to what we term *simple* XPath and XQuery expressions. These represent useful and reasonably expressive fragments which have the advantage of also being amenable to analysis.

The XPath fragment we use disallows a number of features of the full XPath language, most notably the use of any axis other than the child, parent, self or descendant-or-self axes and the use of all functions other than `document()`. Thus, the syntax of a *simple XPath expression e* is given by the following grammar, where s denotes a string and n denotes an element or attribute name:

$$
\begin{array}{rcl}
e & ::= & \text{`document('} \, s \, \text{`)'} \; ((\text{`/'} \mid \text{`//'}) \; p) \mid \\
  &   & \text{`\$delta'} \; (\text{`['} \, q \, \text{`]'})^{*} \; ((\text{`/'} \mid \text{`//'}) \; p)? \\
p & ::= & p \, \text{`/'} \, p \mid p \, \text{`//'} \, p \mid p \, \text{`['} \, q \, \text{`]'} \mid n \mid \text{`*'} \mid \\
  &   & \text{`@'} n \mid \text{`@*'} \mid \text{`.'} \mid \text{`..'} \\
q & ::= & q \, \text{`and'} \, q \mid q \, \text{`or'} \, q \mid e \mid p \mid (p \mid e \mid s) \; o \; (p \mid e \mid s) \\
o & ::= & \text{`='} \mid \text{`!='} \mid \text{`<='} \mid \text{`<'} \mid \text{`>='} \mid \text{`>'}
\end{array}
$$

Expressions enclosed in '[' and ']' in an XPath expression are called *qualifiers*. So a simple XPath expression starts by establishing a context, either by a call to the `document` function followed by a path expression p, or by a reference to the variable `$delta` (the only variable allowed) followed by optional qualifiers q and an optional path expression p. Note that a qualifier q can comprise a simple XPath expression e.

If we delete all qualifiers (along with the enclosing brackets) from an XPath expression, we are left with a path of nodes. We call this path the *distinguished path* of the expression and the node at the end of the distinguished path the *distinguished leaf* of the expression.

The *result* of an XPath expression e is a set of nodes, namely, those matched by the distinguished leaf of the expression. The (simple) *result type* of e, denoted *type(e)*, is one of *string*, element name n or `*`, where `*` denotes any element name. The result type can be determined as follows.

Let p be the distinguished path of e. If the leaf of p is `@`n or `@*`, *type(e)* is *string*. If the leaf of p is n or `*`, *type(e)* is n or `*`, respectively. If the leaf is '.' or '..', *type(e)* is determined from the leaf of a *modified* distinguished path[3] which is defined below.

The *modified distinguished path* is constructed from the distinguished path p of expression e by replacing each occurrence of '.' and '..' from left to right in p as follows. If p starts with `$delta`, then we substitute for `$delta` the distinguished path of the XPath expression which occurs in the event part of the rule. If the step is '..' and it is preceded by 'a/' (where a must be either an element name or `*`), then replace 'a/..' with '.'. If the separator preceding the occurrence of '.' or '..' is '//', then replace the step with '*'. If the step is '.' and the separator which precedes it is '/', then delete the step and its preceding separator.

Example 3 Consider the condition from the ECA rule of Example 2, namely,

```
if $delta[.='Mushroom'] and
   $delta/../..[name='Baghdad Cafe']
```

The result type of the first conjunct is `ingredient` because the event part of the rule is

```
on INSERT document('g.xml')/guide/restaurant/
          entree/ingredient
```

The result type of the second conjunct is `restaurant`, determined as follows. The distinguished path after substituting `$delta` is

```
document('g.xml')/guide/restaurant/entree/
ingredient/../..
```

So we replace '`ingredient/..`' with '.', we delete '`/.`', we replace '`entree/..`' with '.', and finally we delete '`/.`', leaving the modified distinguished path

```
document('g.xml')/guide/restaurant
```

∎

---

[3] The modified distinguished path is simply used to determine the result type; it may not be equivalent to the original path p.

Type inference is part of the XQuery formal semantics defined in [34]. This allows an implementation of XQuery to infer at query compile time the output type of a query on documents conforming to a given input type (DTD or schema). Since XPath expressions are part of XQuery, their result types can also be inferred. Thus, in the presence of a DTD or XML schema, it is possible to infer more accurate result types for XPath expressions using the techniques described in [34][4].

2.5 Simple XQuery Expressions

The XQuery fragment we use disallows the use of full so-called FLWR expressions (involving keywords 'for,' 'let,' 'where' and 'return'), essentially permitting only the 'return' part of an expression [33].

The syntax of a *simple XQuery expression r* is given by the following grammar:

$$
\begin{array}{rcl}
r & ::= & e \mid c \\
c & ::= & \text{'<'} \; n \; a \; (\text{'/>'} \mid (\text{'>'} \; t* \; \text{'</'} \; n \; \text{'>'})) \\
a & ::= & (n \; \text{'='} \; \text{'"'} \; (s \mid e') \; \text{'"'} \; a)? \\
t & ::= & s \mid c \mid e' \\
e' & ::= & \text{'\{'} \; e \; \text{'\}'}
\end{array}
$$

Thus, an XQuery expression r is either a simple XPath expression e (as defined in Section 2.4) or an element constructor c. An element constructor is either an empty element or an element with a sequence of element contents t. In each case, the element can have a list of attributes a. An attribute list a can be empty or is a name equated to an attribute value followed by an attribute list. An attribute value is either a string s or an *enclosed expression e'*. Element contents t is one of a string, an element constructor or an enclosed expression. An enclosed expression e' is an XPath expression e enclosed in braces. The braces indicate that e should be evaluated and the result inserted at the position of e in the element constructor or attribute value.

The *result type* of an XQuery expression r, denoted $type(r)$, is a tree, each of whose nodes is of type n (for element name n), $@n$ (for attribute name n), $*$, $\overline{n//*}$, $*//*$, or *string*. The types with a suffix $//*$ indicate that the corresponding node can be the root of an arbitrary subtree. This is necessary to capture the fact that the results of XPath expressions embedded in r return sets of nodes which may be the roots of subdocuments. The tree for $type(r)$ can be determined as follows. If r is an XPath expression e, then $type(r)$ comprises a single node whose type is $type(e)//*$ if $type(e')$ is n or $*$, or *string* if $type(e')$ is *string*. If r is an element constructor c, then we form a document tree T from c in the usual way, except that some nodes will be labelled with enclosed expressions. For each such enclosed expression e', we determine its result type $type(e')$ in the same way as for the single XPath expression above. We then replace e' in T by $type(e')$. Now $type(r)$ is given by the modified tree T.

The result type of an XQuery expression r denotes a set of trees S such that every tree returned by r is in S (the converse does not necessarily hold because we do not type the results of enclosed expressions as tightly as possible). We call each tree in S an *instance* of $type(r)$. Given an XPath expression e and a tree T, T *satisfies* e if $e(T) \neq \emptyset$. We say that $type(r)$ *may satisfy* e if *some* instance of $type(r)$ satisfies e.

Given XPath expression e and XQuery expression r, it is straightforward to test whether or not $type(r)$ may satisfy e. The test essentially involves checking whether the evaluation of e on the tree of $type(r)$ is empty or not. However, since $type(r)$ denotes a set of trees rather than a single tree, the evaluation needs to be modified as indicated in the following informal description: a node of type *string* in $type(r)$ *may satisfy* any string in e; a node of type $*$ in $type(r)$ *may satisfy* any element name in e; a node of type $n//*$ (respectively, $*//*$) in $type(r)$ *may satisfy* any expression in e which tests attributes or descendants of an element name n (respectively, any element name).

Example 4 Let r be the XQuery expression in the action of the first rule in Example 1, namely

<center><code><store id='{$delta/../@id}'/>.</code></center>

The result type of $delta/../@id is *string*, so $type(r)$ is $store(@id(string))$.

As another example, let r be the XQuery expression

---

[4]Although the `parent` function in [34], which corresponds to a step of '..', always returns the type `anyElement?`.

```
<a><b>{$delta/..}</b><c/></a>
```

and assume that the result type of `{$delta/..}` is `*`. Then $type(r)$ is $a(b(*//*))(c)$. ∎

2.6 ECA Rule Execution

In this section we describe informally the ECA rule execution semantics, giving sufficient details for our purposes in this paper. We refer the interested reader to [7] for a fuller discussion.

The input to ECA rule execution is an XML database and a *schedule*. The schedule is a list of *updates* to be executed on the database. Each such update is a pair

$$(a_{i,j}, docsAndDeltas_i).$$

The component $a_{i,j}$ is an action from the actions part of some rule r_i. The component $docsAndDeltas_i$ is a set of pairs $(d, deltas_{d,i})$, where d is the identifier of a document upon which $a_{i,j}$ is to be applied and $deltas_{d,i}$ is the set of instantiations for the `$delta` variable generated by the event and condition part of rule r_i with respect to document d.

The rule execution begins by removing the update at the head of the schedule and applying it to the database. For each rule r_i, we then determine its set of candidate documents generated by this update, together with the set $deltas_{d,i}$ for each candidate document d. For all rules r_i that have fired (i.e. whose set of candidate documents is non-empty) we place their list of actions $a_{i,1}, \ldots, a_{i,n_i}$ at the head of the schedule, placing the actions of higher-priority rules ahead of the actions of lower-priority rules[5]. Each such action $a_{i,j}$ is paired with the set $docsAndDeltas_i$ consisting of the set of candidate documents for rule r_i with the set of instantiations $deltas_{d,i}$ for each such document d.

The execution proceeds in this fashion until the schedule becomes empty. Non-termination of rule execution is a possibility and thus rule analysis techniques are important for developing sets of 'well-behaved' rules.

3 Analysing ECA Rule Behaviour

Analysis of ECA rules in active databases is a well-studied topic and a number of analysis techniques have been proposed, e.g. [4, 5, 6, 8, 9, 10, 11, 16], mostly in the context of relational databases. Analysis is important, since within a set of ECA rules, unpredictable and unstructured behaviour may occur. Rules may mutually trigger one another, leading to unexpected (and possibly infinite) sequences of rule executions.

Two important analysis techniques are to derive *triggering* [4] and *activation* [10] relationships between pairs of rules. This information can then be used to analyse properties such as *termination* or *confluence* of a set of ECA rules, or reachability of individual rules. The triggering and activation relationships between pairs of rules are defined as follows:

A rule r_i *may trigger* a rule r_j if execution of the action of r_i may generate an event which triggers r_j.

A rule r_i *may activate* another rule r_j if r_j's condition may be changed from False to True after the execution of r_i's action.

A rule r_i *may activate* itself if its condition may be True after the execution of its action.

Thus, two key analysis questions regarding ECA rules are:

1. Is it possible that a rule r_i may trigger a rule r_j ?

2. Is it possible that a rule r_i may activate a rule r_j ?

Once triggering and activation relationships have been derived, one can construct graphs which are useful in analysing rule behaviour:

---

[5] In common with the SQL3 standard for database triggers [24] we assume that no two rules can have the same priority. This, together with our use of restricted sub-languages of XPath/XQuery, ensures that rule execution is deterministic in our language, up to the order in which new sub-documents are inserted below a common parent.

A *triggering graph* [4] represents each rule as a vertex, and there is a directed arc from a vertex r_i to a vertex r_j if r_i *may trigger* r_j. Acyclicity of the triggering graph implies definite termination of rule execution. Triggering graphs can also be used for deriving rule reachability information, by examination of the arcs in the graph.

An *activation graph* [10] again represents rules as vertices and there is a directed from a vertex r_i to a vertex r_j if r_i *may activate* r_j. Acyclicity of this graph also implies definite termination of rule execution.

The determination of triggering and activation relationships between ECA rules is more complex in an XML setting than for relational databases, because determining the effects of rule actions is not simply a matter of matching up the names of updated relations with potential events or with the bodies of rule conditions. Instead, the associations are more implicit and semantic comparisons between sets of path expressions are required. We develop some techniques below.

3.1 Triggering Relationships between XML ECA rules

In order to determine triggering relationships between our XML ECA rules, we need to be able to determine whether an action of some rule may trigger the event part of some other rule. Clearly, `INSERT` actions can only trigger `INSERT` events, and `DELETE` actions can only trigger `DELETE` events.

3.1.1 Insertions

For any insertion action a of the form

$$\texttt{INSERT } r \texttt{ BELOW } e_1 \texttt{ [BEFORE|AFTER } q]$$

in some rule r_i and any insertion event ev of the form

$$\texttt{INSERT } e_2$$

in some rule r_j, we need to know whether ev is *independent* of a, that is, e_2 can never return any of the nodes inserted by a.

The simple XQuery r defines which nodes are inserted by a, while the simple XPath expression e_1 defines where these nodes are inserted. So, informally speaking, if it is possible that some initial part of e_2 can specify the same path through some document as e_1 and the remainder of e_2 "matches" r, then ev is not independent of a. We formalise these notions below, based on tests for containment between XPath expressions [19, 20, 30].

A *prefix* of a simple XPath expression e is an expression e' such that $e = e'/e''$ or $e = e'//e''$. We call e'' the *suffix* of e and e'. Recall from Section 2.5 that, for XQuery r, $type(r)$ denotes the result type of r, and we can test whether or not $type(r)$ may satisfy an XPath expression e.

Given XPath expressions e_1 and e_2, we say that e_1 and e_2 are *independent* if, for all possible XML documents d, $e_1(d) \cap e_2(d) = \emptyset$.

Now let us return to the action a and event ev defined above. Event ev is independent of action a if for all prefixes e_2' of e_2, either

(1) e_1 and e_2' are independent, or

(2) $type(r)$ cannot satisfy e_2''.

Equivalently, we can say that rule r_i (containing action a) may trigger rule r_j (containing event ev) if for some prefix e_2' of e_2, e_1 and e_2' are not independent and $type(r)$ may satisfy e_2''.

From arbitrary simple XPath expressions e_1 and e_2, we can construct an XPath expression $e_1 \cap e_2$ such that for all documents d, $e_1(d) \cap e_2(d) = (e_1 \cap e_2)(d)$. This is done by converting the distinguished paths of e_1 and e_2 to regular expressions, finding their intersection using standard techniques [21], and converting the intersection back to an XPath expression with the qualifiers from e_1 and e_2 correctly associated with the merged steps in the intersection. The resulting expression for $e_1 \cap e_2$ may have to use a union of path expressions (denoted $p_1 \mid p_2$) at the top level, as permitted by XPath [32].

9

We can test whether $e_1 \cap e_2$ is unsatisfiable, and hence whether e_1 and e_2 are independent, by checking whether $e_1 \cap e_2$ is contained in an unsatisfiable expression, using the containment test developed in [19] (which allows unions of path expressions).

Example 5 Recall the two rules from Example 1. Let us call them Rule 1 and Rule 2. For $i = 1, 2$, the form of each rule is

```
on INSERT e_i
if c_i
do INSERT r_i BELOW f_i AFTER TRUE
```

where

- e_1 is `document('s.xml')/stores/store/product`,

- r_1 is `<store id='{$delta/../@id}'/>` and

- f_1 is `document('p.xml')/products/`
  `product[@id=$delta/@id]`

while

- e_2 is `document('p.xml')/products/product/store`,

- r_2 is `<product id='{$delta/../@id}'/>` and

- f_2 is `document('s.xml')/stores/`
  `store[@id=$delta/@id]`.

Now let $e_i = e_i'/e_i''$, $i = 1, 2$, where e_1' is

$$\text{document('s.xml')/stores/store,}$$

e_1'' is `product`, e_2' is `document('p.xml')/products/product` and e_2'' is `store`. So f_2 and e_1' are not independent. Furthermore, $type(r_2)$ is `product(@id(string))` which may satisfy e_1''. We conclude that Rule 2 may trigger Rule 1. A similar argument shows that Rule 1 may trigger Rule 2.

On the other hand, if event e_1 were modified to

$$\text{document('s.xml')/stores/store/product[name]}$$

so that the inserted product had to have a `name` child, then f_2 and e_1' are still not independent. However, now $type(r_2)$ cannot satisfy e_1'' since the `product` node in $type(r_2)$ does not contain a `name` child. In this case, we would detect that Rule 2 could not trigger the modified Rule 1. ∎

3.1.2 Deletions

Similarly to insertions, for any deletion action a of the form

$$\text{DELETE } e_1$$

belonging to a rule r_i, and any deletion event ev of the form

$$\text{DELETE } e_2$$

belonging to a rule r_j, we have that r_i may trigger r_j if ev is not independent of a.

The test for independence of an action and an event in the case of deletions is simpler than for the insertion case above. Let e be the XPath expression $e_1//*$. Event ev is independent of action a if expressions e and e_2 are independent (which can be determined as in Section 3.1.1).

3.2 Activation Relationships between XML ECA rules

In order to determine activation relationships between ECA rules, we need to be able to determine

(a) whether an action of some rule r_i may change the value of the condition part of some other rule r_j from False to True, in which case r_i may activate r_j; and

(b) whether all the actions of a rule r_i will definitely leave the condition part of r_i False; if not, then r_i may activate itself.

Without loss of generality, we can assume that rule conditions are in disjunctive normal form, i.e. they are of the form

$$(l_{1,1} \text{ and } l_{1,2} \ \ldots \ \text{and } l_{1,n_1}) \text{ or } (l_{2,1} \text{ and } l_{2,2} \ \ldots \ \text{and } l_{2,n_2}) \text{ or}$$

$$\ldots \text{ or } (l_{m,1} \text{ and } l_{m,2} \ \ldots \ \text{and } l_{m,n_m})$$

where each $l_{i,j}$ is either a simple XPath expression c, or the negation of a simple XPath expression, not c.

3.2.1 Simple XPath expressions

The following table illustrates the transitions that the truth-value of a condition consisting of a simple XPath expression can undergo. The first column shows the condition's truth value before the update, and the subsequent columns its truth value after a non-independent insertion (NI) and a non-independent deletion (ND):

before	after NI	after ND
$True$	$True$	$True$ or $False$
$False$	$True$ or $False$	$False$

For case (a) above, i.e. when r_i and r_j are distinct rules, it is clear from this table that r_i can activate r_j only if one of the actions of r_i is an insertion which is non-independent of the condition of r_j. Let the condition of r_j be the simple XPath expression c.

For c to be True, we require that it returns a non-empty result. Thus, in a sense, the distinguished path of c plays the same role as an XPath qualifier in that we are interested in the existence of *some* path in the document matching the distinguished path. In addition, the insertion of an element whose name occurs only in a qualifier of c can turn c from False to True. For example, the insertion of a d element below /a/b can turn condition /a/b[d]/e from False to True. Thus we need to consider all the qualifiers and the distinguished path in c in a similar way in any test for case (a). Moreover, the use of '..' in a condition is analogous to introducing a qualifier, so we need to rewrite conditions accordingly. For example, the condition a/b/../d is equivalent to a[b]/d. This condition can be turned from False to True if either a d element is added below an a element which has a b element as a child, or a b element is added below an a element which has a d element as a child.

The procedure for determining non-independence of an insertion from a condition, c, involves constructing from c a set C of conditions, each of which is an XPath expression without any qualifiers i.e. a distinguished path. The objective is that condition c can change from False to True as a result of an insertion only if at least one of the conditions in C can change from False to True as a result of the insertion. We start with set $C = \{c\}$ and proceed to decompose c into a number of conditions without qualifiers, adding each one to C.

A single step of the decomposition is as follows:

1. For any u and w, and v an element name n or *,

   - if condition c_i is of the form $uv/..w$, then replace c_i in C by $u./[v]w$;
   - if c_i is of the form $uv//..w$, then replace c_i in C by $u./[v]w$ and $uv//*[*]$.

2. We can delete from c_i steps of the form /. and ./, as well as replacing occurrences of //.// by //, thereby ensuring that . can occur only at the end of c_i preceded by //

3. If $c_i \in C$ is of the form $u[v]w$, where u, v and w are all non-empty, then replace c_i in C by $u[v]$ and uw.

4. If $c_i \in C$ is of the form $u[v]$, where u and v are non-empty, then delete c_i from C and add to C the conditions specified by one of the cases below, depending on the structure of the qualifier v:

   - if v matches nonterminal p from the grammar for simple XPath expressions, then add u/v to C;

   - if v matches nonterminal e, then add e to C;

   - if v matches x 'or' y (where x and y must be qualifiers), then add $u[x]$ and $u[y]$ to C;

   - if v matches x 'and' y (where x and y must be qualifiers), then add $u[x]$ and $u[y]$ to C;

   - if v matches x o y, then if x or y match nonterminal p, add u/x or u/y, respectively, to C, while if x or y match nonterminal e, add x or y, respectively, to C.

The decomposition process continues until all conditions in C are qualifier-free.

Now let one of the actions a from rule r_i be

$$\text{INSERT } r \text{ BELOW } e_1 \text{ [BEFORE}|\text{AFTER } q]$$

As in Section 3.1.1, we determine $type(r)$ and consider prefixes and suffixes of each condition $c_i \in C$, where $c_i = c_i' \cdot c_i''$. Set C of conditions is independent of a if for each $c_i \in C$ and for each prefix c' of c, either

(1) e_1 and c_i' are independent, or

(2) $type(r)$ cannot satisfy c_i''.

If so, then action a cannot change the truth value of condition c in rule r_j from False to True. Equivalently, we can say that rule r_i may activate rule r_j if for some prefix c_i' of some $c_i \in C$, e_1 and c_i' are not independent and $type(r)$ may satisfy c_i''.

Example 6 The conjunction of conditions from the ECA rule in Example 2 can be rewritten as the single condition c:

$$\text{\$delta[.='Mushroom']/../..[name='Baghdad Cafe']}$$

Set C initially comprises just condition c, which, after substituting for $delta (and dropping document('g.xml') for simplicity), is decomposed into the conditions

$$c_1 = \text{/guide/restaurant/entree/ingredient}$$

and

$$c_2 = \text{/guide/restaurant/entree/ingredient/../../name}$$

Condition c_2 is further decomposed into

$$\begin{aligned}
c_3 &= c_1 = \text{/guide/restaurant/entree/ingredient} \\
c_4 &= \text{/guide/restaurant/entree} \\
c_5 &= \text{/guide/restaurant/name}
\end{aligned}$$

Conditions c_3, c_4 and c_5 can be interpreted as stating that the only way an insertion can change condition c from False to True is if an `ingredient` is inserted as a child of an `entree`, an `entree` is inserted as a child of a `restaurant`, or a `name` is inserted as a child of a `restaurant`. The test described above will detect these possibilities and will correctly infer the possible activation relationships. ∎

For case (b) above, a rule r_i activates itself if it may leave its own condition True. From the above table, we see that with the analysis that we have used so far this will be the case for all rules. To obtain more precision, we need to develop the notion of *self-disactivating* rules, by analogy to this property of ECA rules in a relational database setting [9]. A self-disactivating rule is one where the execution of its action makes its condition False.

If the condition part of r_i is a simple XPath expression c, the rule will be self-disactivating if all its actions are deletions which subsume c. For each deletion action

$$\text{DELETE } e_1$$

we thus need to test if

$$e_1//* \supseteq c$$

For the simple XPath expressions to which our ECA rules are constrained in this paper, and provided additionally that the only operator appearing in qualifiers is '=', it is known that containment is decidable [19]. Thus, it is possible to devise a test for determining whether rules are self-disactivating. The decidability of containment for larger fragments of the XPath language is an open problem [19]. However, even if a fragment of XPath is used for which this property is undecidable, it may still be possible to develop conservative approximations, and this is an area of further research.

3.2.2 Negations of Simple XPath expressions

The following table illustrates the transitions that the truth-value of a condition of the form **not** c, where c is a simple XPath expression, can undergo. The first column shows the truth value of the condition before the update, and the subsequent columns its truth value after a non-independent insertion (NI) and a non-independent deletion (ND):

before	after NI	after ND
True	*True* or *False*	*True*
False	*False*	*True* or *False*

For case (a), where rules r_i and r_j are distinct, it is clear from this table that r_i can activate r_j only if one of the actions of r_i is a deletion which is non-independent of the condition of r_j.

Let the condition of r_j be **not** c. We construct the set of conditions C from c as in Section 3.2.1. Now let the action from rule r_i be

$$\text{DELETE } e_1$$

and let e be the query $e_1//*$. We again use the intersection test from Section 3.1.1 in order to check whether e is independent of each of the conditions in C. If so, then e cannot change the truth value of c from False to True. Otherwise, e is deemed to be non-independent of c, and r_i may activate r_j.

For case (b) above, a rule r_i activates itself if it may leave its own condition True. We again need the notion of a self-disactivating rule. If the condition part of r_i is **not** c, the rule will be self-disactivating if all its actions are insertions which guarantee that c will be True after the insertion.

Let an insertion action a from rule r_i be

$$\text{INSERT } r \text{ BELOW } e_1 \text{ [BEFORE|AFTER } q]$$

and let condition c comprise prefix c' and suffix c''. Action a guarantees that c will be True after the insertion if

$$c' \supseteq e_1$$

and *each* of the trees in the set of trees denoted by r satisfies c''. As a result, we need a stronger concept than the fact that $type(r)$ *may satisfy* expression c''.

Recall the construction of the tree $type(r)$ from Section 2.5. We modify the construction of $type(r)$ to leave enclosed expressions which are of type *string* in $type(r)$ instead of replacing them by *string*. We then need to define what it means for a node in $type(r)$ to *satisfy* (rather than *may satisfy*) part of an XPath expression e. A node of type n, @n or * in $type(r)$ *satisfies* element name n, attribute name @n

13

or expression *, respectively, in e. A node of type $n//*$ (respectively, $*//*$) in $type(r)$ *satisfies* element name n (respectively, expression *). A node labelled with an enclosed expression e' in $type(r)$ *satisfies* e' in e.

Example 7 Recall the first rule of Example 1. A prefix of the negated condition is identical to the XPath expression

```
document('p.xml')/products/product[@id=$delta/@id]
```

and so clearly contains it. The corresponding suffix of the negated condition, namely

```
store[@id=$delta/../@id]
```

is satisfied by each of the trees denoted by the XQuery expression

```
<store id='{$delta/../@id}'/>
```

since the value for the `id` attribute is defined by the same expression as used in the suffix. Hence the rule is self-disactivating. The second rule of Example 2 is similarly self-disactivating. ∎

3.2.3 Conjunctions

For case (a), if the condition of a rule r_j is of the form

$$l_{i,1} \text{ and } l_{i,2} \; \ldots \; \text{and } l_{i,n_i}$$

we can use the tests described in the previous two sections for conditions that are simple XPath expressions or negations of simple XPath expressions to determine if a rule r_i may turn any of the $l_{i,j}$ from False to True. If so, then r_i may turn r_j's condition from False to True, and may thus activate r_j.

For case (b), suppose the condition of rule r_i is of the form $l_{i,1} \text{ and } l_{i,2} \; \ldots \; \text{and } l_{i,n_i}$. There are three possible cases:

(i) All the $l_{i,j}$ are simple XPath expressions. In this case, r_i will be self-disactivating if each of its actions is a deletion which subsumes one or more of the $l_{i,j}$.

(ii) All the $l_{i,j}$ are negations of simple XPath expressions. In this case, r_i will be self-disactivating if each of its actions is an insertion which falsifies one or more of the $l_{i,j}$.

(iii) The $l_{i,j}$ are a mixture of simple XPath expressions and negations thereof. In this case, r_i may or may not be self-disactivating.

3.2.4 Disjunctions

For case (a), if the condition of a rule r_j is of the form

$$(l_{1,1} \text{ and } l_{1,2} \; \ldots \; \text{and } l_{1,n_1}) \text{ or } (l_{2,1} \text{ and } l_{2,2} \; \ldots \; \text{and } l_{2,n_2}) \text{ or}$$

$$\ldots \text{or } (l_{m,1} \text{ and } l_{m,2} \; \ldots \; \text{and } l_{m,n_m})$$

we can use the test described in Section 3.2.3 above to determine if a rule r_i may turn any of the disjuncts

$$l_{i,1} \text{ and } l_{i,2} \; \ldots \; \text{and } l_{i,n_i}$$

from False to True. If so, then r_i may turn r_j's condition from False to True and may thus activate r_j.

For case (b), suppose the condition of rule r_i is of the form

$$(l_{1,1} \text{ and } l_{1,2} \; \ldots \; \text{and } l_{1,n_1}) \text{ or } (l_{2,1} \text{ and } l_{2,2} \; \ldots \; \text{and } l_{2,n_2}) \text{ or}$$

$$\ldots \text{or } (l_{m,1} \text{ and } l_{m,2} \; \ldots \; \text{and } l_{m,n_m})$$

Then r_i will be self-disactivating if it leaves False all the disjuncts of its condition. This will be so if

(i) all the $l_{i,j}$ are simple XPath expressions and r_i disactivates all the disjuncts of its condition as in case (i) of Section 3.2.3 above; or

(ii) all the $l_{i,j}$ are negations of simple XPath expressions and r_i disactivates all the disjuncts of its condition as in case (ii) of Section 3.2.3 above.

In all other cases, r_i may or may not be self-disactivating.

4 Conclusions

In this paper we have proposed a new language for defining ECA rules on XML, thus providing reactive functionality on XML repositories, and we have developed new techniques for analysing the triggering and activation dependencies between rules defined in this language. Our language is based on reasonably expressive fragments of the XPath and XQuery standards.

The analysis information that we can obtain is particularly useful in understanding the behaviour of applications where multiple ECA rules have been defined. Determining this information is non-trivial, since the possible associations between rule actions and rule events/conditions are not syntactically derivable and instead deeper semantic analysis is required.

One could imagine using XSLT to transform source documents and materialise the kinds of view documents we have used in the examples in this paper. However, XSLT would have to process an entire source document after any update to it in order to produce a new document whereas we invisage detecting updates of much finer granularity. Also, using ECA rules allows one to update a document directly, wheareas XSLT requires a new result tree to be generated by applying transformations to the source document.

The simplicity of ECA rules is another important factor in their suitability for managing XML data. ECA rules have a simple syntax and are automatically invoked in response to events — the specification of such events is indeed a part of the Document Object Model (DOM) recommendation by the W3C. Also, as is argued in [13], the simple execution model of ECA rules make them a promising means for rapid prototyping of a wide range of e-services.

The analysis techniques we have developed are useful in a context beyond ECA rules. Our methods for computing rule triggering and activation relationships essentially focus on determining the effects of updates upon queries — the 'query independent of update' problem [25]. We can therefore use these techniques for analysing the effects of other (i.e. not necessarily rule-initiated) updates made to an XML database, e.g. to determine whether integrity constraints have been violated or whether user-defined views need to be re-calculated. Query optimisation strategies are also possible: e.g. given a set of pre-defined queries, one may wish to retain in memory only documents which are relevant to computing these queries. As updates to the database are made, more documents may need to be brought into memory and these documents can be determined by analysing the effects of the updates made on the collection of pre-defined queries.

For future work there are two main directions to explore. Firstly, we wish to understand more fully the expressiveness and complexity of the ECA language that we have defined. For example, we wish to look at what types of XML Schema constraints can be enforced and repaired using rules in the language. Secondly, we wish to further develop and gauge the effectiveness of our analysis methods. Techniques such as incorporating additional information from document type definitions may help obtain more precise information on triggering and activation dependencies [31]. We also wish to investigate the use of these dependencies for carrying out optimisation of ECA rules.
